

FIRST ORDER REGGE CALCULUS

JOHN W. BARRETT

21 September 1994

ABSTRACT. A first order form of Regge calculus is defined in the spirit of Palatini's action for general relativity. The extra independent variables are the interior dihedral angles of a simplex, with conjugate variables the areas of the triangles.

There is a discussion of the extent to which these areas can be used to parameterise the space of edge lengths of a simplex.

Regge's equations of motion for Regge calculus [Regge 1961], a discrete version of general relativity, are derived from an intuitively appealing idea about the correct form for an action principle. However the equations are a little complicated, each equation involving a fairly large number of neighbouring edge lengths in a complicated pattern, and involving combinations of polynomials, square roots, and arccosines of these edge lengths. It is desirable from many points of view to understand these equations more fully, and maybe simplify their form. For example, the second order nature of the equations makes implementation of the Cauchy problem for numerical relativity rather complicated [Sorkin 1975, Tuckey 1993].

In quantum gravity, models for three space-time dimensions have been constructed, either involving a path integral [Witten 1988] or in a discrete version as inspired by Regge and Ponzano [1968]. Witten's construction starts with a first order action for gravity. Regge and Ponzano's model has semiclassical limits which involve generalisations of Regge calculus to degenerate metrics [Barrett and Foxon 1994]. The appearance of degenerate metrics is the way in which first order actions for general relativity differ, in a physical sense, from the usual second order Einstein-Hilbert action. These considerations of models of quantum gravity are the main motivation for studying first order actions for Regge calculus.

The Regge action involves computing defect angles, which are 2π minus the sum of dihedral angles. A dihedral angle is the angle between two different faces (3-simplexes) in a 4-simplex. This paper considers the possibility of extending the Regge action by taking the dihedral angles to be independent variables, rather than as just functions of the edge lengths. As far as simplifying or radically restructuring the Regge calculus is concerned, this work has to be regarded as preliminary. It hints at a calculus in which angles play a dominant role.

The simplest signature for the metric to consider is the case of the positive definite metric, in which case the dihedral angles are angles in the ordinary sense of Euclidean geometry. However, it is perfectly possible to consider other signatures. This paper will discuss mainly the Euclidean case. The phenomena associated with Lorentzian angles in Regge calculus are discussed in [Sorkin 1975] and [Barrett and

Foxon 1994]. Also, the dimension of the manifold is taken to be four throughout, for familiarity, but similar constructions may be made in other dimensions.

The first section is a discussion of first order actions for general relativity and a property of the Regge calculus action which is analogous to a property of the first order action for general relativity. Then there is a definition of a first order action for Regge calculus with the edge lengths and dihedral angles as independent variables, but for which the variation has to be constrained. Using a Lagrange multiplier for each simplex, a second action is defined in which each variable can be varied without constraint.

Both of these new actions have as stationary points all of the stationary points of the original Regge action, but there may be extra ones. These extra ones may arise from the discrete ambiguity in reconstructing the ten edge lengths for a 4-simplex from the values of the areas of the ten triangles.

FIRST ORDER ACTIONS

Regge calculus is similar to the second-order formulation of general relativity. This is its original formulation by Einstein and Hilbert, where the metric is the only independent variable in the action. The idea is to introduce something similar to a first order form, where there are more variables, but the equations are simpler, involving only one derivative. It is similar to the idea of introducing two first order differential equations in place of one second order equation.

In general relativity, the Einstein-Hilbert action S is a function of the metric tensor g . Palatini's [1919] action $P(g, \Gamma)$ is a function of the metric and a general torsion-free, but otherwise unrestricted connection Γ , and extends the Einstein-Hilbert action, in the following sense

$$S(g) = P(g, \gamma(g)) \quad (1)$$

where $\Gamma = \gamma(g)$ is the unique metric-compatible connection for g .

Kibble [1961], and Sciama [1962], extended the Einstein-Hilbert action in a second way, by considering a function of the metric and a general metric-compatible, but not torsion-free, connection. Both of these extensions are first order actions for general relativity, in that the action contains only first derivatives. Both have been called Palatini formulations at times, but I prefer to refer to the first one only as a Palatini action. The second one is called the Einstein-Cartan-Sciama-Kibble action.

The possibility of a first order Regge calculus in the spirit of the ECSK action was considered by Drummond [1986] and Caselle, D'Adda and Magnea [1989]. The purpose of this paper is to suggest a second avenue for constructing a first order action, by following the Palatini formalism.

The first order actions have the property that the variational equations on the larger spaces of fields reduce (in the absence of matter) to the usual equations of general relativity for the metric and connection. One has

$$dP = \frac{\partial P}{\partial g} dg + \frac{\partial P}{\partial \Gamma} d\Gamma \quad (2)$$

The vanishing of the second coefficient, $\partial P / \partial \Gamma$, is the variational equation which implies that the connection is the metric compatible one, $\Gamma = \gamma(g)$. This implies

$$\frac{\partial P}{\partial \Gamma}(g, \gamma(g)) = 0$$

Thus, if one takes the Einstein-Hilbert action S , and regards it as a function of two variables, g and Γ , where Γ is constrained, as in (1), then the equation of motion in fact reduces to

$$0 = \frac{dS}{dg} = \frac{\partial P}{\partial g}(g, \gamma(g)), \quad (3)$$

as a consequence of this.

Regge noticed a similar phenomenon to this in Regge calculus. The action is

$$I(g) = \sum_{\sigma^2} |\sigma^2| \left(2\pi - \sum_{\sigma^4 > \sigma^2} \theta(\sigma^4, \sigma^2) \right) \quad (4)$$

where the notation is as follows: σ denotes a simplex, with the superscript indicating the dimension, $a > b$ indicates that simplex a contains b as a face, $|\sigma|$ denotes the length, area, volume etc., of the simplex, and $\theta(\sigma^4, \sigma^2)$ is the interior dihedral angle in σ^4 between the two faces which meet at σ^2 . Also, g is the metric, which is a tuple of squared edge lengths: $g = (\alpha_1, \alpha_2, \dots)$, where α_k is the square of the length of the k -th edge. The area of the 2-simplex and the angles θ are both functions of g .

We also need to consider the function $J(g, \Theta)$ given by replacing each function $\theta(\sigma^4, \sigma^2)$ in (4) by an independent variable $\Theta(\sigma^4, \sigma^2)$ (equation (13) below). The symbol Θ denotes the tuple $(\Theta(\sigma^4, \sigma^2)_1, \Theta(\sigma^4, \sigma^2)_2, \dots)$ for all pairs $\sigma^4 > \sigma^2$ in the manifold. Then,

$$I(g) = J(g, \theta(g)) \quad (5)$$

Regge considered the computation

$$\frac{dI}{dg} = \frac{\partial J}{\partial g} + \frac{\partial J}{\partial \Theta} \frac{\partial \theta}{\partial g} \quad (6)$$

and showed that the second term is in fact vanishing. As before, the notation is a little condensed: g and θ are vectors, and the second term involves multiplying a vector and a matrix together. The situation is obviously similar to that of the Palatini action, and *suggests* that the θ 's might be considered as independent variables. Since

$$\frac{\partial J}{\partial \Theta(\sigma^4, \sigma^2)} = -|\sigma^2| \quad (7)$$

the second term in (6) is

$$- \sum_{\sigma^4} \left(\sum_{\sigma^2 < \sigma^4} |\sigma^2| \frac{\partial \theta(\sigma^4, \sigma^2)}{\partial g} \right) \quad (8)$$

Regge showed [1961, appendix 1] that for a fixed σ^4

$$0 = \sum_{\sigma^2 < \sigma^4} |\sigma^2| \frac{\partial \theta(\sigma^4, \sigma^2)}{\partial g} \quad (9)$$

A simplified proof is presented here, as it is useful in the following

Proof of (9). Let $i, j, \dots$ be vertices of σ^4 . Label the faces of σ^4 by the vertices from σ^4 which are omitted: thus σ_i^3 is the 3-simplex opposite vertex i , σ_{ij}^2 a 2-simplex, etc. Let $\gamma_{ij} = -\cos \theta(\sigma^4, \sigma_{ij}^2)$ for $i \neq j$, $\gamma^{ii} = 1$, and let n_i be the outward unit normal vector to face σ_i^3 . Then $\sum_i |\sigma_i^3| n_i = 0$, and since $\gamma_{ij} = n_i \cdot n_j$

$$0 = \sum_i \gamma_{ij} |\sigma_i^3| \quad (10)$$

so that the matrix γ has a null eigenvector. Differentiating (10) with respect to the squared edge lengths g and contracting again with this null eigenvector gives

$$0 = \sum_{i \neq j} \sin \theta(\sigma^4, \sigma_{ij}^2) \frac{\partial \theta(\sigma^4, \sigma_{ij}^2)}{\partial g} |\sigma_i^3| |\sigma_j^3| \quad (11)$$

and since one can show by trigonometry that

$$\sin \theta(\sigma^4, \sigma_{ij}^2) |\sigma_i^3| |\sigma_j^3| = \frac{4}{3} |\sigma^4| |\sigma_{ij}^2| \quad (12)$$

the result follows.

INDEPENDENT DIHEDRAL ANGLES

Unlike Palatini's action, $J(g, \Theta)$ cannot be considered as our first order action with g and Θ the independent variables. This is because, according to (7), the equation of motion one would get by putting the variation with respect to Θ equal to zero would imply that the area of every 2-simplex was zero, and so the metric of the 4-simplex would be very degenerate. However the preceeding proof of equation (9) works because for each 4-simplex there is a constraint amongst the θ 's, or in other words, the range of the functions θ forms a submanifold of co-dimension one in the space $\mathbb{R}^{10}$ of the Θ 's for the 4-simplex. Equation (9) shows that the tangent vectors w_i which lie in this surface are the ones which satisfy $\sum_i w_i |\sigma_i^2| = 0$.

Therefore the "first order" stationary action principle for Regge calculus can be stated as follows:

Restricted Variation. The action

$$J(g, \Theta) = \sum_{\sigma^2} |\sigma^2|(g) \left(2\pi - \sum_{\sigma^4 > \sigma^2} \Theta(\sigma^4, \sigma^2) \right) \quad (13)$$

is varied subject to the condition that for each 4-simplex σ^4 the variables $\{\Theta(\sigma^4, \sigma_{ij}^2)\}$ be the dihedral angles of a (different) 4-simplex metric.

The "equations of motion" are the equations which give a stationary point of the action under this variation. In (13), the area of a 2-simplex has been written $|\sigma^2|(g)$ to emphasise that this is a function of the squared edge lengths g . The notation $\text{metric}(\sigma)$ denotes the space of metrics on a simplex; thus $\text{metric}(\sigma^4) \simeq \mathbb{R}^{10}$, and the positive definite ones form a convex cone in this space.

Let us now compute the equations of motion from this action. Introduce a second metric $\hat{g} \in \text{metric}(\sigma^4)$ which is one of the metrics for which the variables $(\Theta(\sigma^4, \sigma_{ij}^2))$ are, by hypothesis, the dihedral angles. Let

be a tangent vector in the space of Θ 's which preserves the constraints. Then, by (9), it satisfies

$$0 = \sum_{\sigma^2 < \sigma^4} |\sigma^2|(\hat{g}) \delta\Theta(\sigma^4, \sigma^2) \quad (14)$$

for each σ^4 . Therefore, using equation (7), the action $J(g, \Theta)$ is stationary for all such variations $\delta\Theta$ only if

$$|\sigma^2|(g) = \mu |\sigma^2|(\hat{g}) \quad (15)$$

for all 2-simplexes in the 4-simplex, with the constant of proportionality μ fixed for each 4-simplex. The other variational equation, for unrestrained variations of the squared edge lengths g , is

$$0 = \frac{\partial J(g, \Theta)}{\partial g} = \sum_{\sigma^2} \frac{\partial |\sigma^2|}{\partial g} \left(2\pi - \sum_{\sigma^4 > \sigma^2} \Theta(\sigma^4, \sigma^2) \right) \quad (16)$$

Clearly, one solution of (15) is that g is proportional to $\hat{g}$ on each σ^4 , which implies that $\Theta = \theta(g)$, and that (16) then reduces to the usual Regge equation of motion. In order to see if this is the only solution, one has to examine (15), and determine whether or not the areas of the 10 triangles of a 4-simplex fix the 10 edge lengths (and hence the dihedral angles) of the simplex uniquely. The situation is as follows.

Proposition. *There is an open convex region $U \subset \text{metric}(\sigma^4) \simeq \mathbb{R}^{10}$ of positive metrics for a 4-simplex, containing all the equilateral 4-simplexes, with the property that if (15) holds for $g, \hat{g} \in U$ and some $\mu > 0$, then g is proportional to $\hat{g}$.*

Proof. Define $\phi: \text{metric}(\sigma^4) \rightarrow \mathbb{R}^{10}$ by $\phi(g) = (|\sigma_{12}^2|^2, |\sigma_{13}^2|^2, \dots)$, the squares of the 10 areas as a function of the squares of the 10 edge lengths. Note that since ϕ is quadratic, condition (15) is equivalent to

$$\phi(g) = \phi(\mu^{\frac{1}{2}} \hat{g})$$

and that if $g, \hat{g}$, satisfy this for some μ and are proportional, then in fact $g = \mu^{\frac{1}{2}} \hat{g}$.

Therefore, it suffices to find an open convex set U such that ϕ is injective on U . The Jacobian matrix $d\phi$ can be computed at the metric which makes each edge length 1, i.e., an equilateral simplex. It is a multiple of

$$\begin{pmatrix} 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 1 & 1 \\ 0 & 0 & 0 & 0 & 0 & 1 & 1 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 & 1 & 0 & 1 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 1 & 1 & 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 1 & 0 & 0 & 0 & 0 & 0 & 1 \\ 0 & 1 & 0 & 1 & 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 1 & 1 & 0 & 0 & 0 & 0 & 1 & 0 & 0 \\ 1 & 0 & 0 & 1 & 0 & 0 & 1 & 0 & 0 & 0 \\ 1 & 0 & 1 & 0 & 0 & 1 & 0 & 0 & 0 & 0 \\ 1 & 1 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 \end{pmatrix},$$

which has determinant 48. The inverse function theorem assures us that there is a convex neighbourhood of this equilateral simplex on which ϕ is injective. By taking

all positive multiples of these metrics, one obtains such a neighbourhood of all the equilateral simplexes.

Unfortunately, the set U cannot cover all of the positive definite metrics. This follows from an example which was discovered by Philip Tuckey. Consider the one parameter family $(t, 1, 1, 1, 1, 1, 1, 1, 1, 1) \in \text{metric}(\sigma^4)$. This is a family of metrics for which one edge has length $\sqrt{t}$ and the rest have length 1. The triangles in this 4-simplex all have edges lengths $(1, 1, 1)$ or $(1, 1, \sqrt{t})$. The squared area of the latter is

$$\frac{1}{8}t(4-t)$$

and so all areas are equal for parameters t and $4-t$.

EXTENDED ACTION

Since the action principle outlined above is the constrained variation of the function J , it is possible to use a Lagrange multiplier technique to allow the variation to be completely unconstrained. To do this, it is necessary to understand the nature of the constraint among the dihedral angles. In turn, this will suggest further ways in which the dihedral angles could be used as completely independent variables.

The results are the following

- (a) The constraint satisfied by the dihedral angles is that the matrix

$$\Gamma_{ij} = \begin{cases} -\cos \Theta_{ij} & i \neq j \\ 1 & i = j \end{cases}$$

has exactly one eigenvector v_i of eigenvalue zero. Any set of numbers $\{0 < \Theta_{ij} < \pi, i \neq j\}$ satisfying this constraint is a set of dihedral angles for some non-degenerate metric on a simplex, which may however not be positive definite.

- (b) Two sets of edge lengths for a simplex have the same set of dihedral angles only if one set is a scalar multiple of the other.

In other words, metrics up to scale are equivalent to sets of angles satisfying the constraint (a).

Proof of (a). The previous section shows that dihedral angles of a positive definite metric simplex do satisfy this constraint. To prove the converse part of the statement, let the (three dimensional) faces of a particular 4-simplex in $\mathbb{R}^4$ be labelled $i = 1, \dots, 5$. The i -th face determines a particular trivector, an element of $\Lambda^3(\mathbb{R}^4)$, by the formula

$$\xi_i = \frac{1}{6}a_1 \wedge a_2 \wedge a_3$$

with the three displacement vectors a_1, a_2, a_3 of the edges sharing any one vertex of the face, arranged in the standard order dictated by an orientation for the simplex. Since the faces form a closed boundary,

$$\sum_{i=1}^5 \xi_i = 0. \tag{17}$$

Now let $\{\Theta_{ij}\}$ satisfy the conditions and v_i be the null eigenvector of Γ_{ij} . An inner product on $\Lambda^3(\mathbb{R}^4)$ is determined by the formula

$$\langle \xi_i, \xi_j \rangle = v_i v_j \Gamma_{ij}. \quad (18)$$

Since the matrix Γ_{ij} has only one null eigenvector, this metric is non-degenerate, and determines a metric on the simplex which induces this metric on $\Lambda^3(\mathbb{R}^4)$. Indeed, in a standard basis, the components of one metric are just a scalar multiple of the inverse of the matrix of the other. With this metric, the volume of the i -th face is $|v_i|$.

Proof of (b). The only arbitrary choice in the previous proof was the scaling of the eigenvector v_i by a positive real number. Therefore the metric on the simplex is determined up to an arbitrary scaling.

For the extended action, one needs to find a suitable function which is zero on the constraint surface for the Lagrange multiplier. The obvious choice is $\det(\Gamma_{ij})$. Using this particular function, the extended action principle is the following:

Extended Variation. The equations of motion are given by the stationary points of the unconstrained variation of the action

$$K(g, \Theta, \lambda) = \sum_{\sigma^2} |\sigma^2|(g) \left(2\pi - \sum_{\sigma^4 > \sigma^2} \Theta(\sigma^4, \sigma^2) \right) + \sum_{\sigma^4} \lambda(\sigma^4) \det(\Gamma_{ij}(\Theta)) \quad (19)$$

with respect to g, Θ , and $\lambda = (\lambda(\sigma^4)_1, \lambda(\sigma^4)_2, \dots)$, in the region where g has positive signature.

Proposition. *The stationary points of K have, in the region where g is a positive definite metric, and $0 < \Theta(\sigma^4, \sigma^2) < \pi$, the same values of g and Θ as the stationary points of the constrained variation of J described above.*

Proof. Variation with respect to g clearly gives the same equation, (16), as before. Variation with respect to λ gives the equations $\det(\Gamma_{ij}) = 0$ for each 4-simplex. As noted before, the matrix γ , calculated from the dihedral angles θ of a metric 4-simplex, has a null eigenvector. Hence $\det(\Gamma) = 0$ is certainly a necessary condition. A computation of the derivative of $\det(\Gamma)$ with respect to Θ_{ij} shows that it is zero if Γ has two independent null eigenvectors, and then the variational equation for Θ becomes $|\sigma^2|(g) = 0$ for every 2-simplex in the 4-simplex. This contradicts our hypothesis that g is a positive definite metric. Thus we are led to the conclusion that Γ has only one independent null eigenvector. Let the null eigenvector be V_i , i.e. $\sum_i \Gamma_{ij} V_i = 0$. Computing the derivative of the determinant, one finds that the variational equation for Θ_{ij} is

$$0 = \frac{\partial K}{\partial \Theta(\sigma^4, \sigma_{ij}^2)} = -|\sigma_{ij}^2|(g) + \kappa \lambda V_i V_j \sin \Theta_{ij} \quad (20)$$

where κ is a non-zero number, constant for each σ^4 . Since $\sin \Theta_{ij} > 0$, and the $|\sigma^2|$ are all positive, it follows that either $V_i > 0$ for all i , or $V_i < 0$ for all i . Since the scaling of the eigenvector was arbitrary, we can choose the sign so that they are all positive.

According to the results at the beginning of this section, the Θ_{ij} determine a metric, $\hat{g}$, for the 4-simplex, for which they are the dihedral angles, and the V_i the volumes of the faces. According to (12), one can simplify (20) so that it becomes the previous equation of motion (15), which asserts that the areas of the triangles computed with g and $\hat{g}$ are proportional.

The use of the dihedral angles considered in this paper suggests some further directions of study. With no restriction at all, a set of dihedral angles specifies a constant curvature metric up to an overall scaling. This suggests that it may be fruitful to consider a calculus based on angles and constant curvature simplexes.
